## ABSTRACT

Notifications are extremely beneficial to users, but they often demand their attention at inappropriate moments. In this paper we present an *in-situ* study of mobile interruptibility focusing on the effect of cognitive and physical factors on the response time and the disruption perceived from a notification. Through a mixed method of automated smartphone logging and experience sampling we collected 10372 *in-the-wild* notifications and 474 questionnaire responses on notification perception from 20 users. We found that the response time and the perceived disruption from a notification can be influenced by its presentation, alert type, sender-recipient relationship as well as the type, completion level and complexity of the task in which the user is engaged. We found that even a notification that contains important or useful content can cause disruption. Finally, we observe the substantial role of the psychological traits of the individuals on the response time and the disruption perceived from a notification.

## INTRODUCTION

Smartphones enable a new form of effortless information awareness. Throughout the day, a smartphone user receives a

variety of information such as email messages, social network events and birthday reminders. Notifications are at the core of this information awareness, as they use audio, visual and haptic signals to steer the user's attention towards the newly-arrived information.

Notifications are extremely beneficial to the users: however, at the same time, they are a cause of potential disruption, since they often require users' attention at inopportune moments. Indeed, previous studies have found that interruptions at inopportune moments can adversely affect task completion time [11, 12, 25], lead to high task error rate [8] and impact the emotional and affective state of the user [5, 7]. Also, users might get annoyed when they receive notifications presenting information that is not useful or relevant to them in the current context [13]. At the same time, studies have shown that users cannot ignore their smartphones for a long time, because they start feeling stressed and anxious about missing important information until they finally pick up the phone to check for any new notifications [26]. This tension is exacerbated by the fact that individuals deal with hundreds of notifications in a day, some of which are disruptive [23]

Previous studies have investigated the user's *receptivity* to mobile notifications [15, 29, 32]. As defined by Fischer [15], receptivity encompasses a user's reaction to an interruption and their subjective experience of it. For instance, users might quickly respond to a notification when they are idle, but they can still get annoyed because of the content of the notification. Previous studies have shown that the user's receptivity to a notification is determined by: (i) how interesting, entertaining, relevant and actionable its content is for the user [15]; (ii) the type of application that triggers it – communication applications are considered as the most important [32]; (iii) time criticality and social pressure [29]. At the same time, some studies have proposed various mechanisms to infer *opportune moments*, i.e., moments in which a user quickly and/or favorably reacts to a notification [14, 23, 28]. In order to infer interruptibility these studies have used machine learning classifiers provided with different contextual

factors including user’s transitions between activities [18], engagement with a mobile device [14], time of day, location and activity [28] as well as notification content [23].

However, none of these studies have deployed the proposed mechanisms in a real world scenario with *in-the-wild* notifications of a regularly used application. The key reason behind this is the fact that the accuracy of these mechanisms is still lower than the user’s expectations. In a real world scenario, the users would not accept a system that might defer or stop an important notification. Previous studies have shown that users are willing to tolerate some interruption, in order to not miss any important information [20]. We believe that interruptibility management systems fail to achieve a very high accuracy in predicting the opportune moment because *there is still a lack of understanding concerning the factors influencing the user’s receptivity to mobile notifications in different physical and cognitive situations.*

In order to bridge this gap, in this work we conduct an in-situ study to collect objective and subjective data about mobile notifications. We designed and developed *My Phone and Me* (Figure 1), an application that uses a novel experience sampling method (ESM) approach to uncover the factors and motivations impacting the user’s reaction and sentiment towards a notification. Through *My Phone and Me*, we collected 10372 notifications, 474 responses for the ESM questionnaires and 11 personality test results from 20 users. Using this data, we investigate users’ interaction with mobile notifications in different physical and cognitive contexts. More specifically, the key contributions of this work are the investigation of:

- the impact of a notification’s alert modality on the user’s ability to perceive a notification alert;
- the impact of the alert modality, sender-recipient relationship, presentation of a notification, the ongoing task type, completion level and task complexity on the response time;
- the impact of the sender-recipient relationship, and the ongoing task’s type, completion level and complexity on the perceived disruption;
- the role of the sender-recipient relationship, notification content and the perceived disruption on the user’s decision to accept or dismiss a notification;
- the impact of the user’s personality on the perceived disruption and response time to a notification.

The findings of our study are wide-ranging, and may have a direct impact on the way future notification management mechanisms are constructed. First, we observe that a sender-recipient relationship, notification priority and an ongoing task’s type and complexity influence the response time for the notification, but there is no impact of the ongoing task completion level on the response time. Moreover, our results show that the recipient’s relationship with the sender of a notification, the ongoing task’s type, completion level and complexity influence the perceived disruption. Our findings imply that the higher the level of disruption perceived by the user the higher the probability of the notification being dismissed. From our results, we also observe that, nevertheless,

**Figure 1. My Phone and Me application: (a) main screen, (b) phone usage statistics, (c) application usage statistics, (d) daily notifications.**

users tend to click highly disruptive notifications if they contain valuable information. While users are aware of notifications even when their phone is in silent mode, our analysis shows that the alert modality has a significant impact on the time taken by the users to view the notification. Finally, we observe the substantial role of psychological traits on how a person reacts to a mobile notification, calling for highly personalized interaction between a smartphone and its user.

## REASONING ABOUT USERS’ RECEPTIVITY TO MOBILE NOTIFICATIONS

An interruption tries to steer a user from an ongoing task to the secondary task signaled by it [8]. As suggested by Clark [10], users can respond to an interruption in four possible ways: (i) handle it immediately; (ii) acknowledge it and agree to handle it later; (iii) decline it (explicitly refusing to handle it); (iv) withdraw it (implicitly refusing to handle it).

A user can respond to mobile notifications in a fairly different way as compared to an in-person interruption. For communication-related interruptions, for example, users might perceive more disruption from an in-person interruption than from a mobile notifications because of the presence of an interrupter in the former case. Mobile notifications enable flexibility in the way an interruption is handled because of the lack of the physical presence of the sender and the asynchronous nature of mobile messaging communication<sup>1</sup>. Thus, the exact moment of handling an interruption can be negotiated and the recipient can decide when and how to attend to a notification.

<sup>1</sup>Certain social norms and expectations from the sender side, however, constrain the flexibility that the receiver has in reacting to a message [30].

**Figure 2.** The three time measurements of a notification captured by the My Phone and Me application. The time of notification arrival (a), the time when a notification is seen (b), and the time when the user accepted (c1) or dismissed (c2) a notification. The time difference between (a) and (b) is *seen time* and the time difference between (b) and (c1 or c2) is the *decision time*.

However, this flexibility introduces many other issues. First, notifications can go unnoticed when a user does not register an alert. Second, usually non-persistent notifications may be forgotten about – a user riding a bicycle, might decide to attend to a notification once they arrive at the destination, yet forget to do so. Finally, although designed to signal an interruption but not interrupt themselves, mobile notifications can still induce unnecessary disruption to a user’s routine. For instance, the disruption can happen when a user decides to attend to a notification immediately, despite being in the middle of another task, only to find that the notification is about an unrelated promotional offer. Moreover, a disruption may happen even if a notification is not attended to, as the thought of a lingering notification may interfere with the user’s current task performance [33].

In this study, we investigate the factors influencing the user’s response to a mobile notification, where the response is defined by the time taken to register and react to a notification, and the way in which the notification is handled (i.e., clicked or dismissed). Moreover, we investigate the user’s motivation for being self-disruptive by clicking the disruptive notifications.

Our assumption is that the response time for a notification and the disruption perceived by the user are influenced by the different aspects of the notification as well as the user’s context. To capture this measure we developed an Android experience sampling method (ESM) application that monitors the actual notifications users receive on their phone, records their reaction to notifications and then queries the users to identify their rating of the disruption caused by the notification. We augment this with questions about the motivation for handling a notification in a particular way. Further, our ESM questionnaires ask the user to provide data on the type, complexity and the completion level of the ongoing task and the user’s relationship with the sender. Finally, we collect participants’ personality trait measures at the end of the experiment.

First, we investigate the ability of users to adjust their response times to a notification, and see how quickly they can triage different notifications in different situations. As shown in Figure 2, we take three time measurements for each notification: the time of notification arrival (a), the time when the notification is seen (b), and the time when the user accepted (c1) or dismissed (c2) the notification. Note that in order to detect the moment at which a notification is seen, we use the unlock event of the phone and assume that all newly available

notifications in the notification bar are seen when the user unlocks the phone. In case a notification arrives when the user is already using the phone (i.e., the phone is unlocked), the seen time of this notification would be computed as zero. We term the time from the notification arrival until the moment the notification was reacted upon as *the response time* for the notification. For our analysis, we break the response time into two intervals:

- Seen time (ST) – time from the notification arrival until the time the notification was seen by the user.
- Decision time (DT) – time from the moment a user saw a notification until the time they acted upon it (by clicking, launching its corresponding app or swiping to dismiss).

We examine the way interruption timing, with respect to the primary task, determines the user’s response to the notification. Moreover, we are interested in the way users triage disruptive notifications. Can users quickly discern when notifications are disruptive? We hypothesize that humans might still attend to a notification, even if they know that the primary task is going to be disrupted. For example, in their study of WhatsApp notifications, Pielot et al. [30] show how, due to an inner pressure raised by social expectations, users quickly respond to instant messaging (IM) communication or frequently check their phones, inducing self interruptions just in order to satisfy the social expectations. In our work, we are looking beyond just IM notifications and investigate the way any disruptive message is handled. Through our ESM study we identify the motivation behind reacting to a disruptive notification and the reasoning and the external factors that lead to the exact reaction.

We aim for a comprehensive investigation of interruptibility from a user perspective, thus comparing the effect of different aspects of a notification on its response time and disruptiveness. Finally, we investigate the potential role of individual psychological traits on how users perceive and react to disruptive notifications.

## DATA COLLECTION

In order to investigate the nature of disruptive notifications and factors that determine the user’s receptivity to mobile notifications in different physical and cognitive situations, we conducted an in-situ field study. More specifically, we developed an Android app called *My Phone and Me* – an Android experience sampling method (ESM) application that collects information about *in-the-wild* notifications, users’ interaction

Group	Features
Time	Arrival, seen and the removal time of a notification.
Notification response	Whether the notification was clicked or dismissed.
Notification details	Sender application and the title of a notification.
Alert type	Signals used by a notification to alert the user: sound, vibrate, and flashing LED.
Context data	Physical activity, location, presence of surrounding sound, WiFi connectivity, proximity to the phone, surrounding light intensity. This data is collected on arrival and removal of a notification from the notification bar.

**Table 1. Description of features from the My Phone and Me dataset.**

with them in natural situations (while they are performing their day-to-day activities), and the physical and cognitive context details.

The My Phone and Me application uses Android’s Notification Listener Service [1] to access notifications and Google’s Activity Recognition API [3] and ESSensorManager [22] to obtain the context information. Table 1 lists the groups of features captured by the application. The collected context data has not been explored for the analysis presented in this paper. To infer the user’s response to a notification, the My Phone and Me application checks whether the application that triggered the notification was launched after the removal time of that notification. We are aware that some notifications are dismissed because they do not require any further action. For this reason, we capture seen time and use the difference between seen time and removal time to understand how long it takes for the user to read and react to a notification.

To collect subjective data from users, the My Phone and Me application triggers four questionnaires in a day. A questionnaire is triggered only when a notification is handled; it contains questions about why the notification was clicked or dismissed by presenting a screenshot of that notification. The application triggers a questionnaire for a randomly selected notification in every four hours time window between 8.00 am and 8.00 pm and the last questionnaire at a random time between 8.00 pm and 10.00 pm. The application did not trigger any questionnaire after 10pm so that the participants do not feel annoyed at responding to the surveys late at night. The application automatically used the local time zones because it relies on the phone’s time. Moreover, if the user is busy, the questionnaire can be dismissed by simply swiping it from the notification bar and no questionnaire is shown to the user for the next 30 minutes.

A questionnaire comprises seven multiple-choice and two free-response questions. The list of questions and their options are shown in Table 2. Since we ask the users to enter the free form text for two questions, it could increase time to respond to a questionnaire and may become a source of annoyance. Therefore, the application allows the users to dictate the responses to these questions. These answers are then converted to text using Android’s SpeechRecognizer API [2].

Additionally, the My Phone and Me application asks the users to take a personality test based on the 50 item Big-Five Factor Markers from the International Personality Item Pool, de-

Question	Options
Did you notice the alert (e.g., vibration, sound, flashing LED) for this notification when it first arrived?	(i) Yes, and I decided to check my phone immediately. (ii) Yes, but I was already using my phone. (iii) Yes, but I ignored the alert. (iv) No, I didn’t notice the alert.
How did you handle the notification when you first saw it?	(i) I decided to immediately click it. (ii) I decided to dismiss it because it didn’t require any further action. (iii) I decided to dismiss it because it was not relevant or useful. (iv) I decided to return to it later. (v) Other (descriptive).
Select all factors that made you decide to click/dismiss the notification.	(i) The sender is important. (ii) The content is important. (iii) The content is urgent. (iv) The content is useful. (v) I was waiting for this notification. (vi) The action demanded by the sender does not require a lot of effort. (vii) At this moment, I was free. (viii) Other (descriptive).
What best describes your relationship to the sender?	(i) Partner (ii) Immediate family (children, parents) (iii) Extended family (nieces/nephews, cousins, aunts/uncles) (iv) Friend (v) Acquaintance (vi) Superior at work (vii) Colleague (viii) Subordinate at work (ix) Client (x) Service provider (xi) Sender is not a person (xii) Other relationship (descriptive).
Please describe what the notification was about.	Descriptive response.
Please describe what activity you were involved with when you received the notification.	Descriptive response.
When the notification arrived, I was:	(i) Starting a new task/activity. (ii) In the middle of a task/activity. (iii) Finishing a task/activity. (iv) Not doing anything.
The task/activity I was doing when the notification arrived was complex.	Five-level Likert scale rating between "strongly disagree" and "strongly agree".
I found the notification disruptive.	Five-level Likert scale rating between "strongly disagree" and "strongly agree".

**Table 2. Questions and their options from questionnaire triggered by the My Phone and Me app.**

veloped by Goldberg [16]. A notification to take this test is triggered once the user has responded to 28 questionnaires. A user can also take the test at any time by clicking on the personality test button present in the application’s action bar.

### Recruitment of the Participants

The My Phone and Me application was published on the Google Play Store from 12th August 2015. It was installed by 74 participants without any monetary incentive. As shown in Figure 1, My Phone and Me tells the users about their addiction to the phone. It allows users to check statistics on their phone usage and interruptions. The application visualizes a user’s phone activities based on different criteria, such as their hourly phone usage (Figure 1 C), hourly usage of individual applications (Figure 1 D) and how much they interact with notifications (Figure 1 B). We believe that displaying this information has a minimal interference with users’ actual behavior for interacting with notifications, but provides a valuable functionality in order to make the users keep the application installed on their phones.

In order to ensure privacy compliance, the My Phone and Me application goes through a two-level user agreement to access the user's notifications. Firstly, the user has to give explicit permission as required by the Android operating system. Secondly, the application shows a list of information that is collected and asks for user consent. Moreover, we show the original content of a notification to the user along with the questionnaire in order to avoid any recall bias in the data but we do not collect the notification content for privacy reasons.

## DATASET

The data collection was carried out for around two months, during which we collected 19494 notifications, 611 responses for the questionnaire (comprising a set of nine questions listed in Table 2) and 11 personality test results (50 item-based Big-Five Factor Markers by Goldberg [16]) from 74 users who installed the My Phone and Me application. Many users stopped responding to the questionnaires after a few days and some did not respond at all. Therefore, we select a subset of the data for the analysis and include data of users who responded to at least 14 questionnaires. There are 20 users who satisfied this constraint. So, our final dataset comprises of 10372 notifications, 474 questionnaire responses and 11 personality test results. Additionally, during the setup phase we asked participants to enter their age and gender: in our dataset there are 11 male and 9 females aged between 19 and 50 years old. However, we do not ask them to provide any other demographic information.

As we are primarily using the questionnaire responses, we compared the click rate (i.e., percentage of notifications that are clicked out of total notifications) of the overall notifications with the notifications that were linked to questionnaires. The click rate for overall notifications is 62.52%, and for notifications linked with questionnaires is 70.04%. Note that a notification is considered to be clicked either when it is clicked on the notification bar or when its corresponding application is launched directly.

We are aware that our dataset has potential limitations that stem from the inherent nature of an *in-the-wild* study. The dataset remains unbalanced because it is not possible to obtain an equal number of questionnaire responses from all users for each test category. For instance, there is a very small chance that our application triggers a questionnaire for each type of sender from the recipients social circle. Furthermore, in practice, a user might not even receive notifications from each of the sender types during the period of the study. Therefore, we use the data from 20 users who responded to at least 14 questionnaires, i.e., the minimum number of questionnaires that were answered by users in this set. We also make an hypothesis of data independence (i.e., data instances are obtained from different users) which might not hold in reality and can be tested only in a controlled setting.

## UNDERSTANDING RESPONSE TIME

In this section we investigate the effect of different factors on the seen and decision time of a notification.

*The key findings of this section are:*

- Users are aware of the notification alerts even when the phone is in silent mode. However, seen time is fastest when the phone is in vibrate mode and slowest for silent mode.
- Notifications are seen fastest when the user is commuting and slowest when idle.
- User's attentiveness increases (reducing the seen time) with the increase in the complexity of an ongoing task.
- The decision time is higher for the notifications from less frequently contacted senders.
- High-priority notifications get quicker response.

## The Role of Alert Modality in Perceiving a Notification Alert

A notification can alert the user by means of vibration, sound and/or flashing LED. In order to investigate how users perceive alerts with different alert modalities, we used the responses provided by the users for Q1 (*Did you notice the alert (e.g., vibration, sound, flashing LED) for this notification when it first arrived?*). According to our dataset, when the notifications (with which the questionnaires were linked) were triggered the user's phone was for 25.54% of the times in the silent mode, 21.50% vibrate mode, 41.94% sound mode and 11.03% sound with vibrate.

Users reported that they missed notification alerts for 14.63%, 15.38%, 23.75%, 21.05% of times their phone was in silent, vibrate, sound, and sound with vibrate mode respectively. This provides evidence that when the phone is in silent mode users are still aware of the notification alerts.

## What Factors Influence the Seen Time?

We investigate the role of alert modality, sender and the ongoing task type, complexity and completion level, in influencing the seen time of a notification.

### *The Impact of Alert Modality on Seen Time*

In order to perform this analysis, from our dataset of 10372 notifications we use all the notifications of the 20 users who responded to at least 14 questionnaires. However, we ignore the notifications that arrived when the user was already engaged with the phone because we could not calculate the seen time of these notifications. This leaves us with 4929 notifications. A one-way Analysis of Variance (ANOVA) of the seen time was carried out for each alert modality. The results show that the alert modality has an impact on the seen time of notifications, with  $F(3, 4925) = 26.41$ ,  $p < 0.001$ . A Tukey post-hoc test (by setting the  $\alpha = 0.05$ ) revealed that the seen time is statistically significantly higher for silent notifications (average 7.332 mins). The seen time for the notifications alerting with vibrate only mode is the lowest (average 3 minutes and 21 second). Sound only and sound with vibrate notifications are the second (average 5 minutes and 57 seconds) and third (average 4 minutes and 50 seconds) most quickly seen by users. Quite interestingly, a recent 15-user study by Pielot

et al. [29] also found that notifications tend to be seen faster when the phone is in the vibrate mode. Here, we confirm this finding, but also point to the above missed notification percentage in the silent mode (14.63%) and show that setting the phone to silent does not help in escaping interruptions.

#### *The Impact of Ongoing Task Type on Seen Time*

To investigate the impact of the ongoing task on the notification's seen time, we require the type of task that the users were involved with when the notification arrived. We classified the information users provided through ESM questionnaires about the ongoing task into the following six categories: work, communication, traveling, maintenance/personal, leisure and idle. The classification was done manually, by two coders who initially disagreed on five entries. Two common labels for these were found after a discussion with three other coders. Note that our app allows users to skip the step of providing the information on the question about their current task by selecting the "Prefer not to say" option. In such cases, we discard the entry from our analysis of the effect of the ongoing task on interruptibility.

A one-way ANOVA of the seen time is carried out for each task type. The results show that the ongoing task type has an impact on the seen time of notifications, with  $F(5, 217) = 2.963$ ,  $p = 0.013$ . A Tukey post-hoc test (by setting the  $\alpha = 0.05$ ) reveals that the seen time is the lowest when the notifications arrive while the user is communicating (average 47 seconds) and highest while the user is idle (average 9 minutes and 30 seconds). Other task types do not have a statistically significant effect on the seen time of notifications and have an average seen time of 5 minutes 45 seconds. As shown in a recent study [31] notifications are more welcome when recipients are bored. However, our results show that while the users might be willing to accept more notifications when idle, the time needed to attend to such notifications might be higher compared to the time needed to attend to a notification while a user is busy.

#### *The Impact of Ongoing Task Complexity on Seen Time*

To analyze the effect of ongoing task complexity, we first encode the reported task complexity, which was reported as a value on the Likert scale (*Strongly disagree*=1, *Somewhat disagree*=2, *Neutral*=3, *Somewhat agree*=4 and *Strongly agree*=5) to the question "The task/activity I was doing when the notification arrived was complex". The Spearman's rank correlation coefficient is computed to evaluate the relationship between the complexity of an ongoing task and the seen time of a notification. The results show that there is a weak, negative correlation between the two variables,  $\rho = -0.183$ ,  $p = 0.005$ . Thus, the increase in the seen time of notifications is correlated with the decrease in rating of ongoing task's complexity. We believe that this correlation exists because the users become more alert while performing a complex task and thus, quickly perceive the interruptions. On the other hand, when the users are not performing any complex task, they become less attentive to the interruptions. Finally, we found that factors such as the completion level of the ongoing task and the sender type do not have a statistically significant effect on the seen time of notifications.

#### **What Factors Influence the Decision Time?**

We analyze the effect of the type, complexity and completion level of the ongoing task, and the sender type on the time a user takes to decide how to react to a notification. We find that neither of these factors have a statistically significant effect on the decision time of notifications with the exception of the sender.

A one-way repeated measures ANOVA of the decision time was carried out for each sender type. The results show that the sender type has an impact on the seen time of notifications with  $F(10, 212) = 2.429$ ,  $p = 0.00936$ . A Tukey post-hoc test (by setting the  $\alpha = 0.05$ ) revealed that out of the 11 sender types (shown in Table 2), notifications from partner lead to the fastest decision time (mean DT is 3.315s), followed by immediate family members with an average decision time of 4.891 seconds. On the other hand, notifications from extended family members and service providers have the largest decision time, 11.93 and 8.146 seconds respectively. There was no statistically significant difference in the decision time of the notifications from other senders. These results demonstrate that notifications are quickly handled when they are sent by the close relatives of the user. In other cases users take more time in reading the content before deciding how to handle it. We hypothesize that this behavior stems from the content of notifications from close friends or family members, which might be more predictable, and a part of a daily routine (e.g., "pick kids from school"). *On the other hand, the users have to spend more time on the notifications from less frequently contacted sources, as the content may be less familiar to them.*

#### **The Role of Notification Presentation**

In our dataset, 2953 (out of 7795) notifications were received when the user was engaged with the phone. Out of these 2953 notifications, 860 are so-called "low-priority" while 2093 are "high-priority" notifications [4]. Here, a high-priority notification is a foreground notification that gets in the way of the user's ongoing activity and the user cannot perform any action to get it out of the way without clicking or dismissing it (e.g. Viber messages). A low-priority one simply appears on the notification bar without getting in the way of the user's ongoing activity (e.g. Gmail notifications).

We investigate the effect of the notification presentation on the response time (i.e., the sum of seen time and decision time) of a notification. The result of a two sample t-test shows that there is a statistically significant effect of notification priority on the response time,  $t(2951) = 17.694$ ,  $p < 0.001$ , with high-priority notifications getting quicker response than low-priority notifications. The mean response time for high-priority notifications is 11.94s versus 25.91s for low-priority notifications.

#### **WHY A NOTIFICATION BECOMES DISRUPTIVE**

In this section we investigate the effect of different factors on the perceived disruption. Since the perceived disruption was measured with a 5-point Likert scale, we encode the responses as: *Strongly disagree*=1, *Somewhat disagree*=2, *Neutral*=3, *Somewhat agree*=4 and *Strongly agree*=5.

*The key findings of this section are:*

- Perceived disruption increases with the increase in the complexity of an ongoing task.
- Notifications are perceived as most disruptive if they arrive when the user is in the middle of or finishing a task, and least disruptive if the user is idle or starting a new task.
- Messages from subordinates and system messages (where the sender is not a person) are considered as most disruptive. Whereas, extended family members are considered as the least disruptive.

### **The Role of Ongoing Task Complexity**

We investigate whether the complexity of an ongoing task is associated with the perceived disruption reported by the users. A Kendall's Tau correlation coefficient was computed to assess the relationship between the ongoing task complexity and perceived disruption. We found a strong, positive correlation between the two variables,  $R\tau = 0.477$ ,  $p < 0.001$ . This demonstrates that the users are likely to get more disrupted by a notification that arrives when they are engaged in an intricate task and less disrupted when they are performing a simple task. In our preliminary analysis [27] we have found that when users are engaged in complex tasks they also express more of a negative sentiment towards interruptions.

### **The Role of Ongoing Task Completion Level**

A one-way ANOVA of the reported disruption was carried out for each class of task completion level (starting, in the middle, finishing and not doing anything). The results show that the completion level of an ongoing task has a significant impact on the disruption perceived by the users from the notifications,  $F(3, 451) = 19.43$ ,  $p < 0.001$ . A Tukey post-hoc test (by setting  $\alpha$  as 0.05) reveals that the perceived disruption is the highest when the user is currently involved in a task. The perceived disruption is the lowest when the user is starting a task or idle and there is no statistically significant difference between these groups. These results show that the perceived disruption when the user is highly engaged in a task is very high not only from the desktop notification, as discussed for example in [13, 24], but also from the mobile notifications.

### **The Role of Sender**

We compute a one-way ANOVA of the reported disruption for each type of sender (see Table 2). According to the results,  $F(10, 444) = 3.987$ ,  $p < 0.001$ , the type of sender has a significant impact on the disruption perceived by the users from the notifications. A Tukey post-hoc test (by setting the  $\alpha$  as 0.05) reveals that the perceived disruption is highest when the sender is not a person or is a subordinate at work (no statistically significant difference between these two groups) and the lowest when the sender is an extended family member. Moreover, colleagues and service providers are the second most disruptive sender groups. There is no significant difference between the other groups. Previous studies showed that users express a negative *sentiment* towards the messages not

coming from their family and friends [15], and that the more "distant" the sender is, the less likely it is that a notification will be *clicked on* [23]. Results from our study complement this with the finding that the perceived *disruption* varies with the sender of a notification.

### **The Role of Ongoing Task Type**

A one-way ANOVA of the reported disruption is carried out for each type of ongoing task (see Table 2). The results show that the type of task that the user is engaged with on the arrival of a notification has a significant impact on the disruption the user perceives when the notification arrives,  $F(5, 380) = 13.03$ ,  $p < 0.001$ . A Tukey post-hoc test (by setting  $\alpha = 0.05$ ) revealed that the perceived disruption is the highest when the user is working and the lowest while the user is idle. After work, traveling and then leisure are the tasks where the users perceive the highest level of disruption. When the users are not idle, they perceive least disruption while communicating and doing a personal or maintenance task. Since the communication can involve notifications themselves, e.g. two mobile users exchanging WhatsApp messages, the above result is not surprising. As shown in a recent study [31], users are receptive to information when they are bored. Our results are in line with these findings in showing that perceived disruption is lowest when the user is idle.

## **UNDERSTANDING THE ACCEPTANCE OF NOTIFICATIONS**

In this section we investigate the factors that make the users accept (click) or dismiss a notification.

*The key findings of this section are:*

- Likelihood of the acceptance of a notification decreases with the increase in the perceived disruption.
- Disruptive notifications are accepted because they contain useful information.

### **Procedure**

Through the questionnaires, we asked the users the reason for clicking/dismissing a notification (see Table 2). If a notification (linked with the questionnaire) is clicked by the user, we ask them to select all factors that made them decide to click the notification, otherwise, we ask them to select the factors that made them decide to dismiss the notification. We provide a predefined list of seven and six options for clicking (see Table 3) and dismissing (see Table 4) the notification. In addition, there is a box for open-ended answers in case users do not find an appropriate answer in the provided list.

In Table 3 and Table 4 we calculate the percentage of times each factor was reported as a reason for clicking and dismissing the notifications. Since, users may select more than one option, the total count percentage in the table adds up to more than 100%. According to these responses, the users mostly accept notifications when they are free, but also the importance of the sender and the usefulness of the content make

Option	Count (%)
Sender is important	31.546
The content is important	27.129
The content is urgent	14.511
The content is useful	31.546
I was waiting for this notification	15.773
The action demanded by the sender does not require a lot of effort	20.189
At this moment, I was free	37.224

**Table 3. User response about why they accept (click) notifications.**

Option	Count (%)
Sender is not important	19.565
The content is not important	40.580
The content is not urgent	43.478
The content is not useful	38.406
The action demanded by the sender does require a lot of effort	3.623
At this moment, I was busy	19.565

**Table 4. User response about why they dismiss notifications.**

them accept a notification. On the other hand, users avoid attending to notifications that do not contain important, urgent or useful content. These responses demonstrate that the value of content is used for deciding whether to click or dismiss a notification. Moreover, the users very rarely state that they were busy and thus had to dismiss a notification. This could indicate that the users give precedence to a notification over the primary task, but only if the content is valuable.

#### Disruptive Notifications are Likely to be Dismissed

We examine the impact of the disruption caused by the notifications on their likelihood of being accepted. In order to quantify this, we encoded the response for perceived disruption with the following values: *Strongly disagree*=1, *Somewhat disagree*=2, *Neutral*=3, *Somewhat agree*=4 and *Strongly agree*=5. In order to detect the acceptance of a notification, we check whether it was clicked by the user. In case it was dismissed, we cross-validate the user's response for the question *How did you handle the notification?* If the user responded that *I decided to dismiss it because it didn't require any further action*, we mark this notification as accepted. Finally, we use 0 to indicate that the notification is dismissed and 1 for an accepted notification.

We fit a logistic regression model to estimate the effect of perceived disruption on the likelihood of the acceptance of notifications. The model was statistically significant  $X^2(1) = 48.3$ ,  $p < 0.001$ . The results indicate the likelihood of the acceptance of a notification decreases by 0.581 times (95% confidence interval limits for the slope were [0.497, 0.675]) for a unit increase in the perceived disruption (based on the 5-point Likert scale).

However, the coefficient of determination for the fitted model is not high ( $R^2 = 0.1434$ ), which implies that not only the disruption perceived by the user, but also other factors influence the user's decision to accept a notification.

#### Why are disruptive notifications accepted?

As discussed above, the disruption perceived by the user makes a notification more likely to be dismissed. Our dataset

Option	Count (%)
Sender is important	25.926
The content is important	33.333
The content is urgent	20.370
The content is useful	35.185
I was waiting for this notification	11.111
The action demanded by the sender does not require a lot of effort	16.667
At this moment, I was free	18.519

**Table 5. User response about why they accept disruptive notifications.**

Variable	Estimated Coefficient	Std. Error	t value	p value
Extroversion	0.017481	0.005694	3.070	0.0278*
Agreeableness	-0.012833	0.005387	-2.382	0.0630
Conscientiousness	0.005942	0.004420	1.344	0.2366
Neuroticism	0.008659	0.004042	2.142	0.0851
Openness	-0.003114	0.005369	-0.580	0.5870
N=11				
$R^2 = 0.737$				
$F(5,5)=2.802(p=0.01413)$				

**Table 6. Results of linear regression with the average disruption as a dependent variable and the personality traits as independent variables.**

shows that 104 out of 474 notifications (with which the questionnaires were linked) were reported as disruptive. These are the notifications for which the user *somewhat* and *strongly* agreed that they perceived disruption from these notifications.

However, 54% of these disruptive notifications were accepted (clicked) by the users, regardless of the fact that they caused disruption. To investigate the reason for this, we checked users' responses about the factors that made them click these notifications. Table 5 shows the percentage of times each factor was reported by the users for accepting the disruptive notifications. As users were allowed to select more than one option, the sum of the percentages in the table adds up to more than 100. "Content is important" and "Content is useful" are the most dominant reason provided by the users for clicking the disruptive notifications. This tells us that even the notifications containing important or useful content can cause disruption. We suspect that these notifications may contain valuable information, but they were not relevant at the moment of delivery. However, our study remains limited to make such conclusions and provide an understanding about why users perceive disruption from useful notifications.

#### DOES PERSONALITY MATTER

In this section we investigate the role of personality on the reported disruption, seen time and decision time of notifications. We computed the score for the five personality traits (i.e., the so-called Big Five: Extroversion, Agreeableness, Conscientiousness, Neuroticism and Openness) for each of the 11 users who fully completed the exit questionnaire that includes the 50 questions related to personality traits. For this computation, we used the scoring instructions that come with the personality test [16].

#### Impact on Reported Disruption

To quantify the relationship between the five personality traits and the disruption perceived by the users from notifications, we fit a linear regression model with the average disruption

Variable	Estimated Coefficient	Std. Error	t value	p value
Extroversion	0.44042	0.14926	2.951	0.0319*
Agreeableness	0.25281	0.14122	1.790	0.1334
Conscientiousness	-0.42050	0.11586	-3.629	0.0151*
Neuroticism	-0.39663	0.10597	-3.743	0.0134*
Openness	-0.05059	0.14074	-0.359	0.7339

N=11  
 $R^2=0.9007$   
 $F(5,5)=9.073(p=0.01511)$

**Table 7. Results of linear regression with the average seen time as a dependent variable and the personality traits as independent variables.**

as a dependent variable, and the five personality traits as independent variables. Here, the average disruption is computed as a mean of disruption reported by the user through the questionnaires. All responses were encoded with the following values *Strongly disagree*=1, *Somewhat disagree*=2, *Neutral*=3, *Somewhat agree*=4, and *Strongly agree*=5. Table 6 shows the parameters of the fitted linear regression model. The results show that the extroversion personality trait significantly affects the average perceived disruption and that extroverts are more inclined to be disrupted by a notification. The high value for the coefficient of determination ( $R^2 = 0.737$ ) shows that the value of average disruption reported by the users is highly influenced by the personality of users, albeit this could be a consequence of our small sample size.

#### Impact on Notification's Seen Time and Decision Time

We then investigate whether the personality traits influence the seen and decision time. In order to perform these analyses, we compute:

1. the average seen time of notifications for each user: the average time taken by a user to view a notification. It is computed as the mean of the seen time of all notification received by the user.
2. the average decision time of notifications for each user: the average time taken by a user to click/dismiss after viewing a notification. It is computed as the mean of decision time of all notifications received by the user.

We first fit a linear regression model with the average (per user) seen time as a dependent variable, and the five personality traits as independent variables. The parameters of the fitted linear regression model are shown in Table 7. The results demonstrate that the time in which a notification is viewed by the users is significantly influenced by their Extroversion, Conscientiousness and Neuroticism personality traits. We fit another linear regression model with the average decision time as a dependent variable and the five personality traits as independent variables. The parameters of the fitted linear regression model are shown in Table 8, and demonstrate that the decision time for a notification is significantly influenced by the user's Extroversion and Neuroticism personality traits.

The need for individual models of human interruptibility has been identified earlier, both in the desktop office setting [19], as well as with mobile smartphone users [23]. The above results show potential for the interruptibility models to be gen-

Variable	Estimated Coefficient	Std. Error	t value	p value
Extroversion	0.45350	0.13446	3.373	0.0198*
Agreeableness	0.29340	0.12722	2.306	0.0692
Conscientiousness	-0.26102	0.10438	-2.501	0.0544
Neuroticism	-0.36975	0.09547	-3.873	0.0117*
Openness	0.08584	0.12679	0.677	0.5284

N=11  
 $R^2=0.9035$   
 $F(5,5)=9.366(p=0.01411)$

eralized across groups of users who share the same personality traits.

## IMPLICATIONS

### Deferring Notifications

Previous studies show that users perceive more disruption from notifications when engaged in intricate tasks and for the first time we confirm this for mobile settings in a quantitative way. Thus, in order to benefit users, the OS should offer more flexibility to them for setting the busy moments so that only time-critical notifications could be triggered. This would potentially allow interruptibility management (IM) systems to learn patterns to predict the user's engagement with complex tasks and prioritize interruptions accordingly.

### Improving Notification Presentation

We found that users become more attentive at busy moments, but are likely to perceive most notifications as disruptive and dismiss them. However, disruptive notifications tend to be accepted if they contain useful content. The presentation of notification summaries could be adapted to help users quickly decide whether to click or dismiss notifications, e.g. by highlighting notifications from priority contacts or with priority content that is learnt over time by an IM system.

### Building a Personality-Dependent Interruptibility Model

We observed that the perceived disruption, seen and decision time are influenced by the user's personality traits. This demonstrates the potential to take the personality trait into account in interruption models and, for example, generalise interruptibility models across groups of users who share the same personality traits. These findings can be exploited to design more effective machine learning algorithms for intelligent notifications.

## RELATED WORK

Multitasking is fundamental in workplaces, where task switching happens every few minutes [17], but also in the private sphere, where an increasing number of personal computing devices mediate the flow of data, be it of entertainment, social or informative nature. Unfortunately, multitasking is seldom seamless, since the limited amount of human attention is sought by a range of competing tasks/themes. The disruptiveness of interruptions was analyzed by Miata and Norman [24], who were among the first to note and explain its variability with the context and particularly their alignment with respect to the primary task a user is working on.

To explain why the interruptions are disruptive, Altmann and Trafton propose the *Memory for Goals model* that explains how users' intention move the necessary mental state of the problem between the foreground and the background of their attention and how such state deteriorates when kept in the background [6]. The importance of the problem state held in the memory corresponds to the complexity of the primary task and, consequently, recovering after a complex task is more demanding than if a routine task is interrupted [9].

In this paper, to the best of our knowledge we are the first to investigate the role of the task complexity on interruptibility in the mobile context. Our results confirm the theory of Altmann and Trafton and we find that interrupting a complex task remains disruptive in the mobile setting. However, the nature of interruptions in our study is fundamentally different from the above work – our users receive notifications signaling interruptions, and are not “forced” into the interruption, per se. This allows us to investigate more subtle phenomena, such as the relationship between the primary task and the time to register a notification. One of our key findings is that *users working on more mentally demanding tasks need less time to notice a notification*. We hypothesize that the “high alert” state in which a user is when working on a complex task [21] also leads to a more agile reaction to a notification.

Multitasking theories are build upon data acquired in highly controlled environments. In reality, however, mobile users engage in unconstrained communication with their friends and family, move about in different surroundings and get notifications from a range of applications. Shirazi et al. [32] show that there is a high variation in the way a notification is handled depending on the application with which it is associated. Personal communication applications, for example, are preferred and attended to faster, than applications associated with utilities and tools. Personal interests, relevance and actionability of the content are additional qualifiers that impact a user's reaction to a notification [15]. In our recent work we uncover that the content and the sender-recipient relationship play a significant role in the decision to accept a notification [23]. In this study, we further refine the role of the sender and find that the messages from extended family members are perceived as the least disruptive. Moreover, the content is one of the main reasons for accepting the notifications even though they interfere with the user's current task.

## LIMITATIONS

Most limitations of the work presented in this paper stem from our decision to collect data in the wild, with the minimum amount of intervention from our users. For example, when it comes to the computation of the seen time of a notification, remotely, we can only detect if a user unlocked the phone and assume that all notifications were seen. We cannot detect the precise time when a user starts reading a summary of a message from the notification bar. Moreover, in case a notification arrives when the user is already engaged with the phone, we assume that the user has seen the notification. Further, since our users are not confined to a laboratory, we are limited to self-reported level of disruption from a notification. In reality, the impact on the primary task need not

be high even if the perceived disruption level is high. On the other hand, this self perception might be the most important factor that determines the user's long term sentiment towards notifications. When it comes to our ESM sampling, despite being as light as possible (we ask only up to four ESM questionnaires per day from each user), they increase the number of notifications a user sees during the data collection period. The density of notifications negatively impacts the sentiment towards individual notifications [28]. However, we believe that in our case the impact is equally distributed among notifications, and consequently, that the findings about the role of different factors still hold. Finally, while the work is the first to our knowledge to uncover the role of individual psychological traits on mobile interruptibility, it is important to note that we related the traits with the *reported* interruptibility. Therefore, our finding that extrovert people report to be more disturbed by notifications than others, should be interpreted under the fact that general reporting about oneself most likely depends on the person's level of extroversion.

## CONCLUSIONS

In this paper we have presented a study of mobile interruptibility, specifically concentrating on the identification of factors that make an interruption disruptive and the impact on the response time to a notification. The contributions of this study are threefold. First, we have confirmed the validity of some past desktop interruptibility studies in a mobile setting. Second, for the first time, we have investigated the role of notification presentation, sender-recipient relationship and personality for modelling interruptibility. Finally, our work confirms findings from recent interruptibility studies.

Through a mixed method of automated smartphone logging and ESM sampling we have obtained a dataset of *in-the-wild* notifications and ESM reports on notification perception from 20 users. We have analysed the data to show that the response time of a notification in the mobile environment is not only influenced by an ongoing task's type, completion level and task complexity, but also by the notification's alert modality, presentation and sender-recipient relationship. Our results have shown that the presentation of a notification and its alert type, as well as the type, completion level and complexity of a task with which the user is engaged, all impact the seen time. Moreover, the relationship with the sender influences the user's decision on accepting a notification or not. The data also reveals how the sentiment (i.e., perceived disruption) towards a notification varies with the type, completion level and complexity of an ongoing task and the recipient's relationship with the sender. Finally, different people exhibit different reactions and we observe a substantial role of the individual psychological traits on how a person reacts to a mobile notification.

## ACKNOWLEDGEMENTS
